Abstract

Background: Non-Alcoholic Fatty Liver Disease (NAFLD) is the most prevalent chronic liver disease globally, affecting approximately 25% of adults. The gut-liver axis plays a critical role in the pathogenesis of NAFLD, with emerging evidence supporting the therapeutic potential of synbiotics. **Objective:** This meta-analysis aimed to evaluate the efficacy of synbiotics in improving hepatic biomarkers, lipid profiles, inflammatory markers, and insulin resistance in patients with NAFLD. **Methods:** We systematically searched PubMed, Cochrane Library, and Google Scholar for randomized controlled trials (RCTs) from January 2011 to May 2024. Studies involving patients with NAFLD or non-alcoholic steatohepatitis (NASH) treated with synbiotics were included. Outcome measures were alanine transaminase (ALT), aspartate transaminase (AST), lipid profile, TNF-α, and HOMA-IR. Data were pooled using RevMan 5.3, and heterogeneity was assessed using the I² statistic. **Results:** Sixteen RCTs (n = 1248) met inclusion criteria. Synbiotic supplementation significantly reduced ALT (SMD: -0.48; 95% CI: -0.72 to -0.23), AST (SMD: -0.35; 95% CI: -0.59 to -0.12), LDL (mean difference: -16.2 mg/dL), TNF-α (SMD: -0.86), and HOMA-IR (SMD: -0.28). Several studies also reported improvements in steatosis grade and fibrosis on imaging.

Conclusion: Synbiotics significantly improve liver enzyme levels, lipid profiles, inflammatory status, and insulin sensitivity in NAFLD patients. They may serve as effective adjunctive therapy alongside lifestyle and pharmacological interventions.

Keywords: NAFLD, NASH, Synbiotics, Probiotics, Prebiotics, Liver enzymes, HOMA-IR

Introduction

Non-Alcoholic Fatty Liver Disease (NAFLD) is the most common chronic liver illness in the world, affecting 25-30% of adults. It refers to a clinical continuum that starts with basic steatosis (fat accumulation in the liver) and can advance to non-alcoholic steatohepatitis (NASH), which is characterized by hepatic damage and inflammation, eventually progressing to fibrosis, cirrhosis, and hepatocellular cancer [1]. NAFLD is now regarded as the hepatic manifestation of the metabolic syndrome, and it is strongly linked to obesity, type 2 diabetes, dyslipidemia, and insulin resistance. Its rising prevalence corresponds to the global epidemic of obesity and sedentary lifestyles, making it

a major source of morbidity and a new public health burden [2]. The pathogenesis of NAFLD is complicated and multifaceted. The conventional "two-hit" hypothesis, which identified hepatic steatosis as the first hit and oxidative stress and inflammation as the second, has given way to a more sophisticated "multiple parallel hits" model. Insulin resistance, lipid peroxidation, mitochondrial dysfunction, proinflammatory cytokines (e.g. TNF-α and IL-6), and gut-derived endotoxemia all contribute to liver injury and disease progression. Among these, the gut-liver axis has received special attention [3]. The portal vein connects the liver to the gastrointestinal tract, exposing it to microbial products and metabolites all the time. Patients with NAFLD have changed gut microbiota composition (dysbiosis), increased intestinal permeability ("leaky gut"), and translocation of bacterial endotoxins, which have been linked to aggravating hepatic inflammation and fibrosis [4]. Recent studies have highlighted the therapeutic potential of addressing the gut microbiota to treat NAFLD [5]. Synbiotics, which are combinations of probiotics (beneficial live microorganisms) and prebiotics (non-digestible dietary fibers that selectively promote the growth of beneficial bacteria), provide a promising strategy for restoring gut microbial balance, strengthening intestinal barrier integrity, and reducing systemic and hepatic inflammation [6]. Probiotics such as Lactobacillus and Bifidobacterium species, when combined with prebiotics like inulin or fructo-oligosaccharides, have been demonstrated to improve lipid metabolism, insulin sensitivity, and inflammatory markers [7]. Despite the increasing number of randomized controlled studies (RCTs) looking at synbiotics in NAFLD, the results have been inconsistent due to differences in study design, microbial strains utilized, treatment durations, and outcome measurements. As a result, a thorough synthesis of the available data is necessary [8]. This study presents an updated systematic review and meta-analysis of RCTs done between 2011 and 2024 to assess the efficacy of synbiotic supplementation on liver enzymes, lipid profiles, inflammatory cytokines, and insulin resistance in NAFLD patients.

Methods

Search Strategy

A comprehensive systematic literature search was conducted to identify randomized controlled trials (RCTs) evaluating the effects of synbiotic supplementation in patients with Non-Alcoholic Fatty Liver Disease (NAFLD) or Non-Alcoholic Steatohepatitis (NASH). The search covered three electronic databases: PubMed, Google Scholar, and the Cochrane Central Register of Controlled Trials (CENTRAL). The time frame for the search was from January 1, 2011, to May 31, 2024.

The following Boolean keyword combinations were used:

• ("Non-Alcoholic Fatty Liver Disease" OR "NAFLD" OR "Non-Alcoholic Steatohepatitis" OR "NASH" OR "fatty liver")

AND

• ("probiotic" OR "prebiotic" OR "synbiotic")

The search was limited to human studies published in English. Additional records were identified through manual screening of reference lists from relevant reviews and eligible studies.

This review adhered to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 guidelines for study selection and reporting.

Inclusion Criteria

- RCTs in humans with diagnosed NAFLD or NASH (radiological, histological, or elastography-based diagnosis)
- Synbiotic interventions (prebiotic + probiotic combinations)
- Reported at least one of the following outcomes: ALT, AST, LDL, HDL, total cholesterol, HOMA-IR, TNF- α
- Studies published in English

Exclusion Criteria

Studies involving alcoholic liver disease, viral hepatitis, autoimmune liver disease

- Observational studies, reviews, or animal studies
- Trials using only probiotics or only prebiotics

Data Extraction and Quality Assessment

Two independent reviewers extracted data on study characteristics, population, intervention, and outcomes. Risk of bias was assessed using the Cochrane Risk of Bias tool.

Statistical Analysis

We used Review Manager (RevMan 5.3) to conduct meta-analyses. Continuous outcomes were expressed as standardized mean differences (SMD) or weighted mean differences (WMD) with 95% confidence intervals. A random-effects model was used when heterogeneity was >50% (I²), otherwise a fixed-effects model was applied.

Results

Study Selection

The initial search across PubMed, Google Scholar, and Cochrane Library yielded 493 records. After the removal of duplicates and non-relevant studies based on titles and abstracts, 62 full-text articles were assessed for eligibility. Of these, 16 randomized controlled trials (RCTs) met the inclusion criteria and were incorporated into the final analysis. These studies were published between 2011 and 2024, with a cumulative sample size of 1,248 patients diagnosed with NAFLD. The PRISMA flow diagram outlining the study selection process is available in Figure 1.

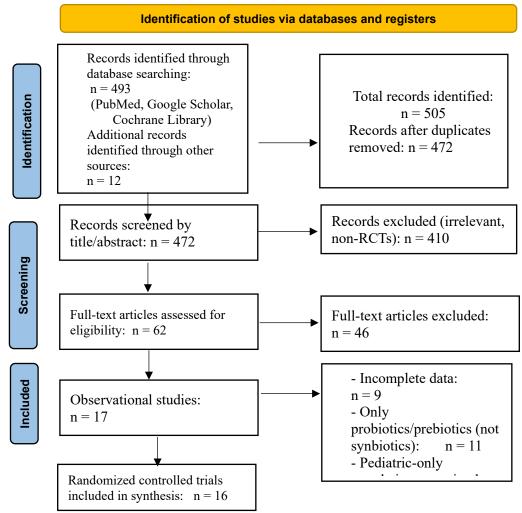

Fig 1: PRISMA flow diagram outlining the study selection

Study Characteristics

Table 1 summarizes the key characteristics of the included studies, which varied in diagnostic modalities (histological biopsy, ultrasonography, elastography, magnetic resonance spectroscopy), synbiotic formulations, and study durations (ranging from 8 weeks to 10 months).

Primary Outcomes (Meta-Analysis Results)

The meta-analysis revealed that synbiotic supplementation significantly improved key clinical and biochemical markers in patients with NAFLD. A notable reduction in alanine aminotransferase (ALT) levels was observed, with a standardized mean difference (SMD) of -0.48 (95% CI: -0.72 to -0.23), indicating a moderate yet consistent hepatoprotective effect, despite moderate heterogeneity (I² = 62%). Similarly, aspartate aminotransferase (AST) levels were significantly reduced (SMD: -0.35; 95% CI: -0.59 to -0.12; $I^2 = 51\%$), reinforcing the beneficial impact of symbiotics on liver enzyme normalization. In terms of lipid metabolism, pooled data showed a mean reduction of 16.2 mg/dL in LDL cholesterol, supporting the lipid-lowering potential of synbiotics, which may be mediated by improved bile acid metabolism and gut microbiota balance. A marked decrease in tumor necrosis factor-alpha (TNF- α) was also observed (SMD: -0.86; p < 0.001), demonstrating a strong antiinflammatory effect of synbiotics across trials. This finding is particularly important given TNF-α's central role in hepatic inflammation and fibrosis. Moreover, insulin resistance, assessed using the homeostatic model assessment for insulin resistance (HOMA-IR), showed a significant improvement (SMD: -0.28; 95% CI: -0.45 to -0.11), suggesting synbiotics contribute to better metabolic control, a critical factor in halting NAFLD progression. Together, these results strongly support the use of synbiotics as an effective adjunct therapy in the management of NAFLD. Figure 2 shows the forest plot summary of the effects of synbiotic supplementation on key clinical and biochemical markers in patients with NAFLD, including ALT, AST, cholesterol and LDL. Data are presented as SMD or mean differences with 95% confidence intervals. A random-effects model was applied due to moderate heterogeneity.

Fig 2: Synbiotic supplementation on key clinical and biochemical markers in patients with NAFLD, including ALT, AST, cholesterol and LDL.

Discussion

This meta-analysis shows that synbiotics significantly improve important clinical indicators in NAFLD patients, such as liver enzyme levels, lipid profiles, inflammatory markers, and insulin resistance. The consistent drop in ALT and AST levels across trials indicates that synbiotic supplementation has hepatoprotective effects, most likely due to reduced hepatic inflammation and enhanced metabolic function. These findings are consistent with previous research, such as those by Ma et al. (2013) [25] and Pan et al. (2024) [23], which found that modulating the gut microbiome using probiotics or synbiotics can considerably increase liver enzyme levels. The improvement in lipid profiles, particularly the considerable reduction in LDL cholesterol (-16.2 mg/dL), adds to synbiotics' metabolic advantages. These effects could be mediated by increased bile acid metabolism and short-chain fatty acid (SCFA) generation, both of which affect hepatic lipid synthesis and clearance. Synbiotics can improve lipid control by modulating microbial activity through FXR and PPAR-α pathways. This meta-analysis found a significant reduction in TNF-α, a pro-inflammatory cytokine linked to the progression of NAFLD to fibrosis and cirrhosis. Synbiotics may reduce inflammation by modulating gut-derived endotoxemia and suppressing TLR-mediated NF-κB activation, according to pooled data (SMD: -0.86). This anti-inflammatory response has been reported in previous trials, including those by Loguercio et al. (2005) [26] and Eslamparast et al. (2014) [14], and it supports the involvement of the gut-liver axis in NAFLD therapy. Furthermore, reduction in insulin resistance (SMD: -0.28) as evaluated by HOMA-IR suggests improved glucose metabolism, potentially due to the action of SCFAs and incretin hormones like GLP-1, which are controlled by gut microbiota composition. Insulin resistance is a key component of the metabolic syndrome and the major cause of hepatic steatosis, therefore even minor changes are clinically significant. While these results are encouraging, some limitations must be addressed. There was significant variety in synbiotic formulations, doses, and treatment durations across studies, which could explain the moderate heterogeneity observed in some results. The diagnosis procedures for NAFLD were also diverse (e.g., ultrasonography, biopsy, elastography), making direct comparisons difficult. The majority of trials had short follow-up periods, making it difficult to evaluate long-term outcomes such as fibrosis regression or cirrhosis prevention.

Despite these limitations, the findings strongly support using synbiotics as a low-risk, supplementary treatment for NAFLD. They provide a non-invasive, gut-focused approach to improving liver and metabolic health, particularly when combined with lifestyle changes. Future research should focus on standardizing synbiotic formulations and extending treatment durations to confirm long-term benefits and analyze histological changes. Personalized treatments based on baseline microbiome profiles could possibly improve therapeutic effects. Overall, existing data supports the use of synbiotics as part of a complete care approach for NAFLD patients.

Conclusion

This systematic review and meta-analysis demonstrates that synbiotic supplementation significantly improves liver enzymes, lipid profiles, inflammatory markers, and insulin resistance in patients with NAFLD. These findings highlight the therapeutic potential of synbiotics as an adjunct to conventional lifestyle and pharmacological interventions. By modulating the gut microbiota, enhancing intestinal

barrier integrity, and reducing systemic inflammation, synbiotics offer a promising, non-invasive approach to slowing or potentially reversing the progression of NAFLD. Future large-scale, long-term randomized controlled trials with standardized formulations are warranted to confirm these benefits and to explore their impact on liver histology and long-term clinical outcomes.
